Chapter 2

Software Engineering

The Institute of Electrical and Electronics Engineers [IEEE] defines the practice of Software Engineering as: "Application of a systematic, disciplined, quantifiable approach to the development, operation and maintenance of software; that is, the application of engineering to software" [14, p. 421]. The word "systematic" in this definition, emphasises the need for a structured process, depicting guidelines and models that describe how software should be developed the most efficient way possible. Such a process does exist and it is often referred to as the Software Development Life Cycle (SDLC) [14, p. 420]. In the absence of a model, i.e. when the developer does what they deem correct without following any rules, the term *Cowboy coding* is used [16, p. 34].

2.1 Software Development Life Cycle

An implementation of the SDLC consists of two major components. First, the process is broken down into several smaller phases. Depending on the nature of the software, it is possible to omit steps or add more steps. I have compiled a simple yet generic approach from multiple sources [7, 13], to which most software projects adhere. This approach consists of five phases.

1. **Requirements phase:** This is the initial phase of the development process. During this phase, the developer gets acquainted with the project and compiles a list of the desired functionalities [13]. Using this information, the developer eventually decides on the required hardware specifications and possible external software which will need to be acquired.
2. **Design phase:** After the developer has gained sufficient knowledge about the project requirements, they can use this information to draw an architectural design of the application. This design consists of multiple documents, including user stories and UML-diagrams.
3. **Implementation phase:** During this phase, the developer will write code according to the specifications defined in the architectural designs.
4. **Testing phase:** This is the most important phase. During this phase, the implementation is tested to identify potential bugs before the application is used by other users.

5. **Operational phase:** In the final phase, the project is fully completed and it is integrated in the existing business environment.

Subsequently, a model is chosen to define how to transition from one phase into another phase. A manifold of models exist [7], each having advantages and disadvantages, but I will consider the basic yet most widely used model, which is the Waterfall model by Benington [2]. The initial Waterfall model required every phase to be executed sequentially and in order, cascading. However, this imposes several issues, the most prevalent being the inability to revise design decisions taken in the second phase, when performing the actual implementation in the third phase. To mitigate this, an improved version of the Waterfall model was proposed by Royce [22]. This version allows a phase to transition to a previous phase, as illustrated in Figure 2.1.

Figure 2.1: Improved Waterfall model by Royce

In this thesis I will solely focus on the implementation and testing phase, as these are the most time-consuming phases of the entire process. The modification to the Waterfall model by Royce is particularly useful when applied to these two phases, in the context of *software regressions*. A regression [21] is a feature that was previously working correctly, but is now malfunctioning. This behaviour can have external causes, such as a change in the system clock because of daylight saving time, but can also be the result of a change to another, seemingly unrelated part of the application code [12].

Software regressions and other functional bugs can ultimately incur disastrous effects, such as severe financial loss or damage to the reputation of the software company. The most famous example in history is without any doubt the explosion of the Ariane 5-rocket, which was caused by an integer overflow [17]. In order to reduce the risk of bugs, malfunctioning components should be detected as soon as possible to proactively defend against potential failures. Because of this reason, the testing phase is to be considered as the most important phase of the entire development process and an application should therefore include sufficient tests. The collection of all tests included in an application, or a smaller chosen subset of certain tests, is referred to

as the *test suite*. Tests can be classified in multiple categories, this thesis will consider three distinguishable categories:

1. **Unit test:** This is the most basic kind of test. The purpose of a unit test is to verify the behaviour of an individual component [23]. The scope of a unit test should be limited to a small and isolated piece of code, such as one function. Unit tests are typically implemented as *white-box tests* [12, p. 12]. A white-box test is constructed by manually inspecting the function under test, to identify important *edge values*. The unit test should then feed these values as arguments to the function under test, to observe its behaviour. Common edge cases include zero, negative numbers, empty arrays or array boundaries that might result in an overflow.
2. **Integration test:** A more advanced test, an integration test verifies the interaction between multiple individually tested components [23]. Examples of integration tests include the communication between the front-end and the back-end side of an application. As opposed to unit tests, an integration test is an example of a *black-box test* [12, p. 6], meaning that implementation-specific details should be irrelevant or unknown when writing an integration test.
3. **Regression test:** After a regression has been detected, a regression test [14, p. 372] is added to the test suite. This regression test should replicate the exact conditions and sequence of actions that have caused the regression, to warn the implementation against subsequent failures if the same conditions would reapply in the future.

A frequently used metric to measure the quantity and effectiveness and thoroughness of a test suite is the *code coverage* or *test coverage* [14, p. 467]. The test coverage is expressed as a percentage and indicates which fraction of the application code is affected by code in the test suite. Internally, this works by augmenting every statement in the application code using binary instrumentation. A hook is inserted before and after every statement to keep track of which statements are executed during tests. Many different criteria exist to interpret these instrumentation results and thus to express the fraction of covered code [20], the most commonly used ones are *statement coverage* and *branch coverage*.

Statement coverage expresses the fraction of code statements that are executed in any test of the test suite [12], out of all executable statements in the application code. Analogously, the fraction of lines covered by a test may be used to calculate the *line coverage* percentage. Since one statement can span multiple lines and one line may also contain more than one statement, both of these criteria implicitly represent the

same value. Statement coverage is heavily criticised in literature [20, p. 37], since it is possible to achieve a statement coverage percentage of 100% on a code fragment which can be proven to be incorrect. Consider the code fragment in Listing 2.1. If a test would call the `example`-function with arguments $\{a = 1, b = 2\}$, the test will pass and every statement will be covered, resulting in a statement coverage of 100%. However, it is clear to see that if the function would be called with arguments $\{a = 0, b = 0\}$, a *division-by-zero* error would be raised, resulting in a crash. This very short example already indicates that statement coverage is not trustworthy, yet it may still be useful for other purposes, such as detecting unreachable code which may safely be removed.

```
1 int example(int a, int b) {  
2     if (a == 0 || b != 0) {  
3         return a / b;  
4     }  
5 }
```

Listing 2.1: Example of irrelevant statement coverage in C.

Branch coverage on the other hand, requires that every branch of a conditional statement is traversed at least once [20, p. 37]. For an `if`-statement, this results in two tests being required, one for every possible outcome of the condition (`true` or `false`). For a `loop`-statement, this requires a test case in which the loop body is never executed and another test case in which the loop body is always executed. Remark that while this criterion is stronger than statement coverage, it is still not sufficiently strong to detect the bug in Listing 2.1. In order to mitigate this, *multiple-condition coverage* [20, p. 40] is used. This criterion requires that for every conditional statement, every possible combination of subexpressions is evaluated at least once. Applied to Listing 2.1, the `if`-statement is only covered if the following four cases are tested, which is sufficient to detect the bug.

- $a = 0, b = 0$
- $a = 0, b \neq 0$
- $a \neq 0, b = 0$
- $a \neq 0, b \neq 0$

It should be self-evident that achieving and maintaining a coverage percentage of 100% at all times is critical. However, this does not necessarily imply that all lines, statements or branches need to be covered explicitly [4]. Some parts of the code might simply be irrelevant or untestable. Examples include wrapper or delegation methods that simply call a library function. All major programming languages have frameworks

and libraries available to collect coverage information during test execution, and each of these frameworks allows the developer to exclude parts of the code from the final coverage calculation. As of today, the most popular options are JaCoCo¹ for Java, coverage.py² for Python and simplecov³ for Ruby. These frameworks are able to generate in-depth statistics on which parts of the code are covered and which parts require more tests, as illustrated in Figure 2.2.

2.2 Agile Software Development

2.2.1 Agile Manifesto

Since the late 1990's, developers have tried to reduce the time occupied by the implementation and testing phases. In order to accomplish this, several new implementations of the SDLC were proposed and evaluated, later collectively referred to as *Agile development methodologies*. The term *Agile development* was coined during a meeting of seventeen prominent software developers, held between February 11-13, 2001, in Snowbird, Utah [10]. As a result of this meeting, the developers defined the four key values and twelve principles that define these new methodologies, called the *Manifesto for Agile Software Development*, also known as the *Agile Manifesto*.

According to the authors, the four key values of Agile software development should be interpreted as follows: "While there is value in the items on the right, we value the items on the left more" [1]. Meyer provides a the following definition for the four values: "general assumptions framing the agile view of the world", while defining the principles as "core agile rules, organizational and technical" [19, p. 2]. Martin identifies the principles as "the characteristics that differentiate a set of agile practices from a heavyweight process" [18, p. 33]. A variety of different programming models, based on the agile ideologies, have arisen since 2001 and each one incorporates these values and principles in their own unique way. I will very briefly explain these values and their corresponding principles, using the mapping proposed by Kiv [15, p. 12].

2.2.1.1 *Individuals and interactions over processes and tools*

Instead of meticulously following an outlined development process and utilising the best tools available, the main focus of attention should shift to the people behind the development and how they are interacting with each other. According to Glass, the quality of the programmers and the team is the most influential factor in the successful development of software [6].

Principle 5: Build projects around motivated individuals. Give them the environment and support they need, and trust them to get the job done.

The key to successful software development is ensuring that the people working on the project are both skilled and motivated. Research has shown that, while proficient programmers can cost twice as much as their less-skilled counterparts, their productivity lies between 5 to 30 times higher [6]. Any factor that negatively impacts a healthy environment or decreases motivation should be changed [18, p. 34].

Principle 6: The most efficient and effective method of conveying information to and within a development team is face-to-face conversation.

Real-life conversations and human interaction, ideally in an informal setting, should be preferred over forms of digital communication. Direct communication techniques will encourage the developers to raise questions instead of making (possibly) wrong assumptions [5, 6].

Principle 8: Agile processes promote sustainable development. The sponsors, developers, and users should be able to maintain a constant pace indefinitely.

The team should aim for a fast, yet sustainable pace instead of rushing to finish the project. This reduces the risk of burnouts and ensures high-quality software will be delivered [18].

Principle 11: The best architectures, requirements, and designs emerge from self-organizing teams.

The idea of requiring a hierarchy within a team should be abolished. Every team member must be considered equal and must have input on how to divide the work and the corresponding responsibilities [18]. Subsequently, Fowler and Highsmith state that a minimal amount of process rules and an increase in human interactions has a positive influence on innovation and creativity [5].

Principle 12: At regular intervals, the team reflects on how to become more effective, then tunes and adjusts its behavior accordingly.

An agile team is versatile and aware that the environment changes continuously, and that they should act accordingly [18]. An important aspect to keep in mind is that the decision on whether to incorporate changes, should be taken by the team itself instead of by an upper hand, since all members share equal responsibilities [6].

2.2.1.2 *Working software over comprehensive documentation*

The primary goal of software engineering is to deliver a working end product which fulfills the needs of the customer. In order to accomplish this, development should start as soon as possible. Traditional programming models demand a lot of documentation to be written prior to the actual development, which will inevitably lead to inconsistencies between the documentation and the actual application as the project grows and the requirements change [9].

Principle 1: Our highest priority is to satisfy the customer through early and continuous delivery of valuable software.

Research has identified a negative correlation between the functionalities of the initial

delivery and the quality of the final release. This implies that the team should strive to deliver a rudimentary version of the project as soon as possible [18], rather than attempting to implement all required features at once.

Principle 3: Deliver working software frequently, from a couple of weeks to a couple of months, with a preference to the shorter timescale.

In the first principle I have explained the importance of an early, rudimental version of the project. After this initial delivery, new functionality is added in an incremental fashion in subsequent deliveries until all required features are implemented, with the interval between two delivery cycles being as short as possible. An important distinction to make is the difference between a “delivery” and a “release”. Deliveries are iterations of the project sent to the customer, while releases are those deliveries that the customer considers suitable for public use [5]. Glass criticises this statement and sees little point in delivering development versions to the customer [6].

Principle 7: Working software is the primary measure of progress.

In traditional software development, the progress is measured by the amount of documentation that has been written. This way of measuring is however not representative for the actual completion of the project. Glass gives the example of a team lacking behind on schedule. They can hide their lack of progress by simply writing documentation instead of code, fooling their management [6]. In agile software development, the progress is measured directly by the fraction of completed functionality [18].

Principle 10: Simplicity –the art of maximizing the amount of work not done– is essential.

Agile software development tries to realise a minimal working version as soon as possible. In order to achieve this goal, optimal time management is crucial. This imposes two important consequences. First, the developers should only start writing code when the design is thoroughly tested, to avoid having to restart all over again [6]. Secondly, as section 2.2.1.4 will explain, it is possible that the structure of the project can change completely, something which needs to be accounted for when writing the code [18].

2.2.1.3 Customer collaboration over contract negotiation

In traditional software engineering, the role of the customer is subordinate to the developer. Agile software engineering maintains a different perception of this role, treating both the customer and developers as equal entities. Daily contact between both parties is of vital importance to avoid misunderstandings and a short feedback loop

allows the developers to cope with changes in requirements and to ensure that the customer is satisfied with the delivered product [9].

Principle 4: Business people and developers must work together daily throughout the project.

Martin: “For a project to be agile, customers, developers and stakeholders must have significant and frequent interaction.” [18]. This has already been emphasised before by the principles discussed in section 2.2.1.1. Note that the word “customer” is missing in the definition of this principle. According to Glass, this was done on purpose to make the agile ideas apply to non-business applications as well [6].

2.2.1.4 Responding to change over following a plan

The first step of the aforementioned waterfall model (section 2.1) was to ensure both the customer and the developers have a complete and exhaustive view of the entire application. In reality however, this has proven to be rather difficult and sometimes even impossible. As a result of this, a change in requirements was one of the most common causes of software project failure [6]. Consequently, the agile software development methodologies do not require a complete specification of the final product to be known a priori and stimulate the developers to successfully cope with changes as the application is being developed [9].

Principle 2: Welcome changing requirements, even late in development. Agile processes harness change for the customer’s competitive advantage.

Due to the iterative development approach, agile methodologies are able to implement required changes much earlier in the process, resulting in only a minimal impact on the system [18].

Principle 9: Continuous attention to technical excellence and good design enhances agility.

“High quality is the key to high speed”, according to Fowler [18]. Code of high quality can only be achieved if the quality of the design is high as well, since this is required to handle changes in requirements. As a consequence, agile programmers should manage a “refactor early, refactor often” approach. While this might not result in a short-term benefit, as no new functionality is added, it definitely has a major impact in the long run and is essential to maintaining agility [5].

2.2.2 The need for Agile

In the wake of the world economic crisis, software companies were forced to devote efforts into researching how their overall expenses could be reduced. This research has concluded that in order to reduce financial risks, the *time-to-market* of an application should be as short as possible. In order to accomplish this, further research was conducted, resulting in an increase of attention for agile methodologies in scientific literature [11]. As was previously described in section 2.2.1.2, agile methodologies strive to deliver a minimal version as soon as possible, allowing additional functionality to be added in an incremental fashion. This effectively results in a shorter *time-to-market* and lower costs, since the company can decide to cancel the project much earlier in the process.

In addition to a reduced time-to-market, maintaining an agile workflow has also proven beneficial to the success rate of development. A study performed by The Standish Group revealed that the success rate of agile projects is more than three times higher compared to when traditional methodologies are practised, as illustrated in Figure 2.3.

Figure 2.3: Success rate of Agile methodologies [8].

2.2.3 Continuous Integration

In traditional software development, the design phase typically leads to a representation of the required functionality in multiple, stand-alone modules. Subsequently, every module is implemented separately by individual developers. Afterwards, an attempt is made to integrate all the modules into the final application, an event to which Meyer refers to as the “Big Bang” [19, p.103]. The name *Big Bang* reflects the complex nature of this operation, since every developer can take unexpected assumptions, resulting in mutually incompatible components.

Contrarily, agile development methodologies advocate the idea of frequent, yet small deliveries (section 2.2.1.2). Consequently, this implies that the code is built often and that the modules are integrated multiple times, on a *continuous* basis, rather than just once at the end. This practice of frequent builds is referred to as *Continuous Integration* [18, 19]. It should be noted that this idea exists and has been applied before the agile manifesto was written. The first notorious software company that has adopted this practice is Microsoft, already in 1989 [3, p.11]. Cusumano reports that Microsoft typically builds the entire application at least once per day [3, p.12], which in turn requires developers to integrate and test their changes multiple times per day.

The introduction of Continuous Integration in software development has important consequences on the life cycle. Where the waterfall model used a cascading life cycle, Continuous Integration employs a circular, repetitive structure consisting of three phases, as visualised in Figure 2.4.

1. **Implementation:** In the first phase, every developer individually writes code for the module they were assigned to. At a regular interval, the code is committed to the remote repository.
2. **Integration:** When the code is committed, the developer simultaneously fetches the changes to other modules. Afterwards, the developer must integrate the changes with his own module, to ensure compatibility. In case a conflict occurs, the developer is responsible for its resolution [18].
3. **Test:** After the module has successfully been integrated, the test suite is run to ensure no bugs have been introduced.

Adopting Continuous Integration can prove to be a lengthy and repetitive task. Luckily, a variety of tools and frameworks exist to automate this process. These tools are typically added as a `post-receive` hook to the version control system (e.g. Git, Subversion, ...). Every time a commit is pushed by a developer, the code is built and tests are executed. I will now discuss four prominent Continuous Integration systems.
